We present a new method for the solution of the behavior of an ensemble of qubits in a random time-dependent external field. The forward evolution in time is governed by a transfer matrix. The elements of this matrix determine the various decoherence times. The method provides an exact solution in cases where the noise is piecewise constant in time. We show that it applies, for example, to a realistic model of decoherence of electron spins in semiconductors. Results are obtained for the non-perturbative regimes of the models, and we see a transition from weak relaxation to overdamped behavior as a function of noise anisotropy.

I. INTRODUCTION

In the last decade, advances in fabrication and experimentation have made it possible to observe and control quantum effects in individual systems that could previously be observed only in the aggregate. One important condition for these advances has been to minimize, or at least to manage, decoherence. Quantum systems are inevitably subject to random influences that destroy coherence, and classical behavior takes over. Only if this can be avoided can we hope to advance the technology of quantum information processing, and theoretical understanding can help to achieve this. Theoretical calculations generally fall into three categories: eactly soluble examples, approximation methods, and numerical computations. The theory of quantum decoherence has been notable for its richness in the last two of these three, but exactly soluble models have been few and far between, though some exceptions may be noted [1],[2],[3]. This paper goes some way towards changing this situation.

Most treatments of decoherence begin with two coupled quantum objects: the system to be observed, and the unmeasured environment to which the system is coupled. The system eventually loses its coherence due to that coupling. The most natural way to treat the problem is to formulate a master equation for the reduced density matrix, which incorporates the system-environment coupling, and also some aspects of the environment's dynamics. This approach can in principle treat the "back-action" of the system on the environment, though this is often difficult in practice. The classic example is the Caldeira-Leggett model [4]

An alternative formulation is to treat the environment as a fixed source of random noise. In this approach it is not possible to take into account back-action. However, there are many physical situations in which back-action is not important. Treating the environment as fixed but random is then usually more convenient. This approach will be used in this paper.

In quantum computation, a large array of qubits - two-level quantum systems - needs to maintain coherence. A necessary requirement for this is to maintain quantum coherence of a single qubit, and most discussions begin at this level. The restriction to a two-state quantum system allows simplifications in the formalism. The purpose of this paper is to show that the decoherence of a two-state system subject to random noise can, under certain conditions, be treated by a powerful transfer matrix method analogous to that of statistical mechanics, allowing us to solve a number of cases exactly. Furthermore, these solutions apply to the non-perturbative situation in which the coupling to the environment is not smaller than the level separation of the qubit. This difficult regime is of great importance since some quantum computation schemes, most notably holonomic quantum computing, propose to operate in this parameter range [5].

In the next section we introduce and solve a class of white-noise-type models that can be solved by a relatively straightforward application of the method. We discuss a simple example, and compare the exact results to perturbation theory. The new results in the non-perturbative regime are also explored. In the third section we extend the method to Markovian models that can also be solved, this time by a slightly more intricate form of the transfer matrix. In the final section we discuss the possible extensions and ultimate limitations of the method.

II. WHITE-NOISE-LIKE MODELS

A. Definition

Our two-level system will be described by the Hamiltonian

$$H = -\vec{B}_0\sigma_z - \vec{b}(t)\cdot\vec{\sigma}, \tag{1}$$

so that the energy separation is $2B_0$ and $\vec{b}(t)$ is a random function. The system is prepared at time $t = 0$ with a 2×2 density matrix $\rho(t = 0) = \rho_0$. The measurable quantities are

$$\overline{\vec{M}(t = t_f)} = \int \mathcal{P}[\vec{b}(t)]\mathcal{D}[\vec{b}(t)]\ Tr\ [\rho_0\vec{\sigma}(t)]\,. \tag{2}$$

Here σ_x, σ_y, and σ_z are the Pauli matrices, which together with the unit matrix represent a complete set

of observables in the qubit space. We work in the Heisenberg representation, so that $\vec{\sigma}(t)$ satisfies $i\, d\vec{\sigma}/dt = [\vec{\sigma}, H]$. $\int \mathcal{P}[\vec{b}(t)]\mathcal{D}[\vec{b}(t)]$ indicates a sum over all possible functions $\vec{b}(t)$ on the interval $t \in [0, t_f]$, with the appropriate probability $\mathcal{P}[\vec{b}(t)]$. The specification of $\mathcal{P}[\vec{b}(t)]$ defines a model in the general category of 'qubits subject to random time-dependent forces.

Our notation is of course motivated by spin qubits. However, it should be obvious that the method and all results apply to any two-level system. In particular, $\vec{B}_0$ and $\vec{b}$ need not be magnetic fields.

We now consider the following form of $\mathcal{P}[\vec{b}(t)]$. Let $\vec{b}(t)$ be piecewise constant with discontinuous jumps at regular intervals of length τ. Furthermore, let $\vec{b}(t)$ be completely independent between time intervals, i.e., $\vec{b}(t) = \vec{b}_1$ and $\vec{B}(t) = B_0\widehat{z} + \vec{b}_1 = \vec{B}_1$ for $0 < t < \tau$, $\vec{b}(t) = \vec{b}_2$ and $\vec{B}(t) = B_0\widehat{z} + \vec{b}_2$ for $\tau < t < 2\tau$, etc. , with no correlation between the different $\vec{b}_i$. Finally, each $\vec{b}_i$ has the same probability distribution $P(\vec{b})$. Let there be m time intervals so that the final time when a measurement is performed is $t_f = m\tau$. For this model, then, we have

$$\begin{aligned}
&\int \mathcal{P}[\vec{b}(t)]\mathcal{D}[\vec{b}(t)] F\left[\vec{b}(t)\right] \\
&\quad = \int d^3b_1 P(\vec{b}_1) \cdots \int d^3b_m P(\vec{b}_m) F\left[\vec{b}(t)\right] \\
&\quad = \overline{F\left[\vec{b}(t)\right]}
\end{aligned}$$

for the average of any functional $F\left[\vec{b}(t)\right]$. $P(\vec{b}) \geq 0$ and $\int d^3b\, P(\vec{b}) = 1$. Any model with the piecewise constant $\vec{b}$ on equally-spaced intervals and the product form for the probability is exactly soluble, as we now show. We shall also give a physical example below, in order to indicate that the model is not artificial.

B. General solution

Defining

$$H_i = -\vec{B}_i \cdot \vec{\sigma} = -\vec{B}_0\sigma_z - \vec{b}_i \cdot \vec{\sigma}$$

and

$$U_i = e^{-iH_i\tau},$$

the solution for $\overline{\vec{\sigma}(t_f)}$ is

$$\overline{\vec{\sigma}(t_f)} = \overline{\vec{\sigma}(m\tau)} = \overline{U_m^+ \cdots U_2^+ U_1^+ \vec{\sigma}(0) U_1 U_2 \cdots U_m}. \quad (3)$$

Once we have $\overline{\vec{\sigma}(t_f)}$ we can apply the initial conditions and obtain results for any observable according to Eq. 2. Because of the statistical independence of the values of $\vec{b}$ at different intervals, the averaging can be done for each correlation time individually, so $\vec{\sigma}_{ij}$ transforms in the time τ into

$$\begin{aligned}
\overline{\vec{\sigma}_{ij}(\tau)} &= \int d^3b_1 P(\vec{b}_1) \overline{\left(U_1^+\right)_{ik} \vec{\sigma}_{kl}(0) \left(U_1\right)_{lj}} \\
&= \overline{\left[\exp\left(iH_1\tau\right)\right]_{ik} \left[\exp\left(-i\vec{H}_1\tau\right)\right]_{lj}} \vec{\sigma}_{kl}(0) \\
&= \overline{\left[E\cos(B_1\tau) - i\widehat{B}_1 \cdot \vec{\sigma}\sin(B_1\tau)\right]_{ik} \left[E\cos(B_1\tau) + i\widehat{B}_1 \cdot \vec{\sigma}\sin(B_1\tau)\right]_{lj}} \vec{\sigma}_{kl}(0),
\end{aligned}$$

and summation over repeated indices is implied. The identity matrix E always transforms into itself: $E(\tau) = E$. We have used the identity $\exp(i\vec{X}\cdot\vec{\sigma}t) = \cos Xt + i\widehat{X}\cdot\vec{\sigma}\sin Xt$, valid for any vector $\vec{X}$. $\widehat{X} = \vec{X}/\left|\vec{X}\right| = \vec{X}/X$. The key to the method is to compute and then iterate the superoperator $\overline{\left[U_1^+(\tau)\right]_{ik} \left[U_1(\tau)\right]_{lj}}$. Performing the average and writing the results in matrix form, we find

$$\overline{\vec{\sigma}(\tau)} = I_0\vec{\sigma}(0) + \sum_{ij} I_{ij}\sigma_i\vec{\sigma}(0)\sigma_j + i\sum_i I_i\left[\vec{\sigma}(0)\sigma_i - \sigma_i\vec{\sigma}(0)\right], \quad (4)$$

where the integrals I_0, I_i and I_{ij} are defined as

$$\begin{aligned}
I_0 &= \int P(\vec{b})\cos^2(B\tau) d^3b \\
I_i &= \int P(\vec{b})\widehat{B}_i \sin(B\tau)\cos(B\tau)\, d^3b \quad (5) \\
I_{ij} &= \int P(\vec{b})\widehat{B}_i\widehat{B}_j \sin^2(B\tau) d^3b.
\end{aligned}$$

Here $\vec{B} = \vec{B}_0 + \vec{b}$, $\widehat{B}_x = b_x/B$, $\widehat{B}_y = b_y/B$, and $\widehat{B}_z = (b_z + B_0)/B$. (Note that $\vec{B}_0$ may be defined so that $I_x = I_y = 0$. In order to exhibit the symmetry of the following expressions, however, we shall retain these quantitities.) Using the properties of the Pauli matrices to simplify the expressions, we find the three operators:

$$\begin{aligned}
\overline{\sigma_x(\tau)} &= (I_0 + I_{xx} - I_{yy} - I_{zz})\,\sigma_x(0) + 2\,(I_{xy} + I_z)\,\sigma_y(0) + 2\,(I_{xz} - I_y)\,\sigma_z(0) \\
\overline{\sigma_y(\tau)} &= (I_0 - I_{xx} + I_{yy} - I_{zz})\,\sigma_y(0) + 2\,(I_{xy} - I_z)\,\sigma_x(0) + 2\,(I_{yz} + I_x)\,\sigma_z(0) \\
\overline{\sigma_z(\tau)} &= (I_0 - I_{xx} - I_{yy} + I_{zz})\,\sigma_z(0) + 2\,(I_{xz} + I_y)\,\sigma_x(0) + 2\,(I_{yz} - I_x)\,\sigma_y(0).
\end{aligned} \tag{6}$$

We may write this in a compact fashion by defining the transfer matrix T by

$$\begin{pmatrix} \overline{\sigma_x(\tau)} \\ \overline{\sigma_y(\tau)} \\ \overline{\sigma_z(\tau)} \end{pmatrix} = \begin{pmatrix} T_{xx} & T_{xy} & T_{xz} \\ T_{yx} & T_{yy} & T_{yz} \\ T_{zx} & T_{zy} & T_{zz} \end{pmatrix} \begin{pmatrix} \sigma_x(0) \\ \sigma_y(0) \\ \sigma_z(0) \end{pmatrix},$$

or

$$\vec{\sigma}(\tau) = T\ \vec{\sigma}(0),$$

for short - it is understood that in expressions of this kind $\vec{\sigma}$ is a column vector. The detailed expressions for the matrix elements are:

$$\begin{aligned}
T_{xx} &= I_0 + I_{xx} - I_{yy} - I_{zz} \\
T_{yy} &= I_0 - I_{xx} + I_{yy} - I_{zz} \\
T_{zz} &= I_0 - I_{xx} - I_{yy} + I_{zz} \\
T_{xy} &= 2I_{xy} + 2I_z \\
T_{yx} &= 2I_{xy} - 2I_z \\
T_{xz} &= 2I_{xz} - 2I_y \\
T_{zx} &= 2I_{xz} + 2I_y \\
T_{yz} &= 2I_{yz} + 2I_x \\
T_{zy} &= 2I_{yz} - 2I_x.
\end{aligned} \tag{7}$$

T is an example of an exactly computable quantum dynamical map. For a definition and general discussion of such maps, see Ref. [6]. At t_f, we find

$$\begin{aligned}
\overline{\vec{\sigma}(t_f)} &= \overline{\vec{\sigma}(m\tau)} \\
&= \int d^3b_m P(\vec{b}_m) U_m^+ \cdots \int d^3b_2 P(\vec{b}_2) \times \\
&\quad \left[U_2^+ \left(\int d^3b_1 P(\vec{b}_1) U_1^+ \vec{\sigma}(0) U_1 \right) U_2 \right] \cdots U_m,
\end{aligned} \tag{8}$$

so this process can be iterated, and we have

$$\vec{\sigma}(t_f) = \vec{\sigma}(m\tau) = T^m\ \vec{\sigma}(0).$$

T is real but generally not symmetric. It operates in the complex three-dimensional vector space of superoperators. Each vector (a_x, a_y, a_z) in the space is associated with the operator $\vec{a} \cdot \vec{\sigma}$.

Diagonalizing T, we find

$$D = RTR^{-1}$$

where $D = diag(d_1, d_2, d_3)$ and the rows of R are the eigenvectors of T. Since T is real, the eigenvalues are the roots of a cubic equation with real coefficients, so at least one of the d_i is real and the other two must either be real, or they must be complex conjugates. Iterating, we have

$$\begin{aligned}
\vec{\sigma}(t_f) &= \vec{\sigma}(m\tau) \\
&= T^m\ \vec{\sigma}(0) \\
&= \left(R^{-1}DR\right)^m \vec{\sigma}(0) \\
&= R^{-1}D^m R\ \vec{\sigma}(0),
\end{aligned}$$

with

$$D^m = \begin{pmatrix} (d_1)^m & 0 & 0 \\ 0 & (d_2)^m & 0 \\ 0 & 0 & (d_3)^m \end{pmatrix}.$$

Recalling that $m = t_f/\tau$ and using index notation, the solution becomes

$$\sigma_i(t_f) = R_{ij}^{-1}\,(d_j)^{t_f/\tau}\,R_{jk}\ \sigma_k(0). \tag{9}$$

This equation, together with Eqs. 5, 7, and 2 constitute an exact solution for all $P(\vec{b})$. The magnitudes of the eigenvalues d_j determine the relaxation times through the relation

$$\frac{1}{T_j} = -\frac{1}{\tau} \ln |d_j|\,, \tag{10}$$

while the transformation matrices R contain the information that allows an experimenter to prepare and measure a particular relaxation time.

C. Realistic Example

A relatively simple example of current interest concerns the spin dynamics of an electron in a two-dimensional system such as an appropriately constructed semiconductor heterostructure. Let the system be subject to an electric field $\vec{E} = E\hat{z}$ and an applied uniform time-independent magnetic field $B_0\hat{z}$ perpendicular to the conducting layer. Due to spin-orbit couping, there is also an effective magnetic field acting on the spin, according to $\vec{b} = \alpha\vec{p} \times \vec{E}$, where the electron momentum $\vec{p}$ lies in the $x-y$ plane. α is a constant and $|\overrightarrow{p}| = p_F$, the Fermi momentum. The electron scatters, causing $\vec{p}$ and therefore $\vec{b}$ to be a random function of time. The magnitudes $|\vec{p}|$ and therefore $\left|\vec{b}\right| = b_0$ are fixed, however. If

we take the scattering events to occur at equally-spaced intervals of length τ, now understood as a time related to the momentum scattering time τ_p, then this situation falls into the class of models considered in this paper. The assumption of equally-spaced intervals is of course an approximation - the actual length of the intervals is random, and is governed by a Poisson distribution. The effective magnetic field is called the Rashba field [7], and the spin relaxation mechanism is known as the DP or D'yakonov-Perel' mechanism [8].

Hence the Hamiltonian for the spin degree of freedom is precisely of the form shown in Eq.1, and in this case $\vec{b}$ lies in the $x-y$ plane. The average over $\vec{b}$ is performed by settting $\vec{b} = b_0(\cos\phi, \sin\phi, 0)$ and averaging uniformly over ϕ. $\vec{B} = B_0\widehat{z}+\vec{b}$. In the physical situation of interest, the environmental correlation time τ is usually much less than the spin relaxation times and also much less than $1/B_0$. Now set $I_x = I_y = 0$, and note that symmetry in the $x-y$ plane also gives $I_{xy} = I_{yx} = I_{xz} = I_{zx} = I_{yz} = I_{zy} = 0$. For this particular case $I_{zz} = 0$ since $b_z = 0$, but it is interesting to keep this quantity for the time being. The transfer matrix simplifies considerably:

$$\begin{aligned} T_{xx} &= I_0 + I_{xx} - I_{yy} - I_{zz} \\ T_{yy} &= I_0 - I_{xx} + I_{yy} - I_{zz} \\ T_{zz} &= I_0 - I_{xx} - I_{yy} + I_{zz} \\ T_{xy} &= -T_{yx} = 2I_z \\ T_{xz} &= I_{zx} = I_{yz} = I_{zy} = 0 \end{aligned} \tag{11}$$

The eigenvalues of T are $d_z = T_{zz} = I_0 - I_{xx} - I_{yy} + I_{zz}$, and $d_{x,y} = I_0 - I_{zz} \pm i\sqrt{4I_z^2 - (I_{xx} - I_{yy})^2}$. In the Appendix we show that these eigenvalues satisfy $|d_3| \leq 1$ and $|d_\pm| \leq 1$, which guarantees that all solutions are exponentially decaying.

The connection to decoherence times is obtained by considering the limit where $t_f >> 1/B_0 >> \tau$ and $t_f >> 1/\left|\vec{b}\right| >> \tau$. Expanding the integrals for small τ, we find

$$d_z \approx 1 - 2\tau^2 \int P(\vec{b}) \left(b_x^2 + b_y^2\right) d^3b = 1 - 2\tau^2 \left(\overline{b_x^2} + \overline{b_y^2}\right) \tag{12}$$

$$\begin{aligned} d_{x,y} \approx & 1 - \tau^2 \int P(\vec{b}) \left(B_0^2 + b^2\right) d^3b + \\ & - \tau^2 \int P(\vec{b}) B_0^2 \; d^3b \pm 2i\sqrt{\tau^2 B_0^2 - (I_{xx} - I_{yy})^2 / 4} \\ = & 1 - 2\tau^2 B_0^2 - \tau^2 \left(\overline{b_x^2} + \overline{b_y^2} + 2\overline{b_z^2}\right) + \\ & \pm 2i\sqrt{\tau^2 B_0^2 - \frac{1}{4}\tau^4 \left(\overline{b_x^2} - \overline{b_y^2}\right)^2} \end{aligned} \tag{13}$$

The result for d_z is independent of the ratio $\left|\vec{b}\right| / B_0$, but the $d_{x,y}$ are sensitive to it. Most experiments are done in the regime where $\left|\vec{b}\right| << B_0$, and we consider this perturbative case first:

$$\begin{aligned} |d_{x,y}| &= \left|1 - 2\tau^2 B_0^2 - \tau^2 \left(\overline{b_x^2} + \overline{b_y^2} + 2\overline{b_z^2}\right) \pm 2i\tau B_0 + O(\tau^4)\right| \\ &\approx 1 - \tau^2 \left(\overline{b_x^2} + \overline{b_y^2} + 2\overline{b_z^2}\right) \end{aligned} \tag{14}$$

If the system is prepared in an energy eigenstate, (in spin language, along the z-direction), then it remains along that direction since $T_{xz} = T_{yz} = 0$, and we find

$$\begin{aligned} \langle\sigma_z(t_f)\rangle &= (d_3)^{t_f/\tau} \, \sigma_z(0) \\ &= \left[1 - 2\tau^2 \left(\overline{b_x^2} + \overline{b_y^2}\right)\right]^{t_f/\tau} \langle\sigma_z(0)\rangle \, . \end{aligned} \tag{15}$$

This is finite in the limit of small $1/b$ and τ if the combination $\tau\left(\overline{b_x^2} + \overline{b_y^2}\right)$ approaches a finite limit, and we have

$$\langle\sigma_z(t_f)\rangle \to \exp\left(-t_f/T_1\right) \langle\sigma_z(0)\rangle \, , \tag{16}$$

with the energy relaxation time T_1 given by

$$\frac{1}{T_1} = 2\tau \left(\overline{b_x^2} + \overline{b_y^2}\right) = 2b_0^2\tau. \tag{17}$$

If the system is prepared in an equal superposition of the energy eigenstates (in spin language, in the x-y plane), then there are oscillations of σ_x and σ_y owing to the fact that the $d_{x,y}$ are not real, at an angular frequency given by ϕ/τ, where $\phi = \left|\tan^{-1}\left(\mathrm{Im}\, d_+ / \mathrm{Re}\, d_+\right)\right|$. There is also exponential decay given by

$$|\langle\sigma_{x,y}(t_f)\rangle| \to \exp\left(-t_f/T_2\right) |\langle\sigma_{x,y}(0)\rangle| \tag{18}$$

with the phase relaxation time T_2 given by

$$\frac{1}{T_2} = \tau \left(\overline{b_x^2} + \overline{b_y^2} + 2\overline{b_z^2}\right) = b_0^2\tau. \tag{19}$$

Note that these results satisfy the constraint that in the isotropic ($B_0 \to 0$) limit $\overline{b_x^2} = \overline{b_y^2} = \overline{b_z^2}$ we must have $T_1 = T_2$, since the distinction between longitudinal and transverse relaxation ceases to have any meaning. Incidentally, the perturbation theory results for the same model except that the time intervals follow Poisson statistics are: $1/T_1 = 4\tau_p \left(\overline{b_x^2} + \overline{b_y^2}\right)$ and $1/T_2 = 2\tau_p \left(\overline{b_x^2} + \overline{b_y^2} + 2\overline{b_z^2}\right)$ [9]. Thus the previous results can be translated over with the identification $\tau = 2\tau_p$.

The rotation matrix R is block-diagonal for this simplified case: $R_{xz} = R_{zx} = R_{yz} = R_{zy} = 0$. This means that preparation and measurement of the spin in the $z-$direction will give T_1 and preparation and measurement of the spin in any direction in the $x-y$ plane will give T_2. Preparation in any other direction will result in independent relaxations of the $z-$ component and the magnitude of the projection of the spin onto the $x-y$ plane. There is no cross-talk between the two relaxations.

D. Comparison with perturbation theory

The usual treatment of problems in this class is by perturbation theory, often going under the name of Redfield theory in this context. The theory has been extensively worked out because of its applications in nuclear magnetic resonance. The condition for the validity of the perturbative approach is $B_0 >> b(t)$ at all times. A detailed treatment is given by Slichter [10]. The results for relaxation times are:

$$\frac{1}{T_1} = k_{xx}(\omega_0) + k_{yy}(\omega_0) \tag{20}$$

$$\frac{1}{T_2} = \frac{1}{2T_1} + k_{zz}(0), \tag{21}$$

with $\omega_0 = 2B_0$ and

$$k_{ii}(\omega) = 2\int_{-\infty}^{\infty} ds\ e^{-i\omega s}\overline{b_i(t)b_i(t+s)}. \tag{22}$$

To compute k_{ii} in the example of the previous subsection, we note that $k_{xx} = k_{yy}$ and $k_{zz} = 0$ and that we must average t uniformly over the interval $(0, \tau)$ and average ϕ uniformly over the interval $(0, 2\pi)$. For the piecewise constant $b(t)$, we find

$$\begin{aligned}\overline{b_i(t)b_i(t+s)} =& b_0^2\overline{\cos[\phi(t)]\ \ \cos[\phi(t+s)]} \\ =& \begin{cases} 0, & \text{if} \quad s < -t \\ b_0^2/2, & \text{if} \quad -t < s < \tau - t \\ 0, & \text{if} \quad s > \tau - t. \end{cases}\end{aligned} \tag{23}$$

This result can be substituted into Eq. 22. In the limit that $B_0\tau << 1$, $k_{xx}(\omega_0) \to b_0^2\tau$, and similarly for $k_{yy}(\omega_0)$. Thus perturbation theory applied to our model yields $1/T_1 = 2b_0^2\tau$ and $1/T_2 = 1/2T_1$, in agreement with Eqs. 17 and 19. Although we have not treated them in detail, the longitudinal fluctuations described by the function k_{zz} that produce dephasing also have the correct perturbative limit [cf. Eqs. 19 and 20].

E. Non-perturbative regime

In this subsection, we wish to investigate the overall behavior of the exact solution. There are four parameters in the model: $\tau, 1/B_0, 1/\left|\vec{b}\right|$, and τ_f. The regime $t_f < \tau$ is of no interest: the spin precesses freely about the random field $\vec{B}_0 + \vec{b}_1$. So we focus on the regime $t_f >> \tau$, and the expression for the observables in Eq. 9. We have already discussed the perturbative regime in which $t_f >> 1/\left|\vec{b}\right| >> 1/B_0 >> \tau$. Our solution is non-perturbative, and remains valid for arbitrary values of $\left|\vec{b}\right|/B_0$, $\left|\vec{b}\right|\tau$ and $B_0\tau$. However, simple expressions are available only in relatively symmetric situations, so let us take $\left|\vec{b}\right| = b_0$ and $I_{xy} = I_{yx} = I_{xz} = I_{zx} = I_{yz} = I_{zy} = 0$, but allow for the possibility that $I_{xx} \neq I_{yy}$, and also that $b_z \neq 0$. We also assume the probability density $P(\vec{b})$posesses well-defined moments up to the fourth order in $\vec{b}$, and that the odd moments vanish. We once again have $d_z = T_{zz} = I_0 - I_{xx} - I_{yy} + I_{zz}$.

Since we have a closed-form solution, we can easily compute higher-order expansions. To see this, take $\left|\vec{b}\right|\tau << 1$ and $B_0\tau << 1$ in order to perform the trigonometric integrals. Then to order τ^4, we have

$$\frac{1}{T_1} = -\frac{1}{\tau}\ln|d_z| = 2\left(\overline{b_x^2} + \overline{b_y^2}\right)\tau + \left\{2\left(\overline{b_x^2} + \overline{b_y^2}\right)^2 - \frac{1}{3}\left[2B_0^2\left(\overline{b_x^2} + \overline{b_y^2}\right) + 2\overline{b_x^4} + 2\overline{b_y^4} + 2\overline{b_x^2 b_y^2} + \overline{b_x^2 b_z^2} + \overline{b_y^2 b_z^2}\right]\right\}\tau^3 \tag{24}$$

The strength of the steady field enters the relaxation rate at order τ^3.

For T_2 there are two possibilities. For $I_z > |I_{xx} - I_{yy}|$, d_x has an imaginary part, $d_{x,y} = I_0 - I_{zz} \pm i\sqrt{4I_z^2 - (I_{xx} - I_{yy})^2}$, $|d_x|^2 = (I_0 - I_{zz})^2 + 4I_z^2 - (I_{xx} - I_{yy})^2$ and

$$\begin{aligned}\frac{1}{T_2} &= -\frac{1}{\tau}\ln|d_x| = -\frac{1}{\tau}\ln|d_y| \\ &= \tau\left(\overline{b_x^2} + \overline{b_y^2} + 2\overline{b_z^2}\right) + \tau^3\left[\left(\overline{b_x^2} + \overline{b_y^2} + 2\overline{b_z^2}\right)^2 - \frac{1}{3}B_0^2 b_+^2 + \frac{1}{3}\left(\overline{b_x^4} + \overline{b_y^4} + 2\overline{b_z^4} + 2\overline{b_x^2 b_y^2} + 3\overline{b_+^2 b_z^2}\right) - \frac{1}{2}\left(\overline{b_x^2} - \overline{b_y^2}\right)^2\right]\end{aligned} \tag{25}$$

again good to order τ^4. This corresponds to a damped oscillatory solution. For $I_z < |I_{xx} - I_{yy}|$, the $d_{x,y}$ are real and the solution is overdamped. All three eigenvalues of T are real, and so there are three relaxation times. T_1 remains as above, and, to order τ^2, we find

$$\frac{1}{T_{2\pm}} = \overline{\left(b_x^2 + b_y^2 + 2b_z^2\right)}\tau \pm \sqrt{\left(\overline{b_x^2 - b_y^2}\right)^2 - 4B_0^4}\tau.$$

Here the spin relaxes so fast that it does not have time

to precess about the external field.

Of particular interest is the fact that this abrupt transition from oscillating to overdamped behavior is driven by the *anisotropy* of the noise. Physically, strong highly anisotropic noise quickly erases the distinction between the clockwise and counterclowise directions about the z-axis, and the spin does not know which way to precess.

The most interesting issue that is accessible for the exact solution is the crossover from the weak-noise regime ($\left|\vec{b}\right| << B_0$) to the strong-noise ($\left|\vec{b}\right| >> B_0$) regime.

We first look at the case of purely transverse noise: $\overline{b_x^2} = \overline{b_y^2}$ and $\overline{b_z^2} = 0$. The probability distribution is again the uniform one for the angle $\theta = \tan^{-1}(b_y/b_x)$ with $b_x^2 + b_y^2 = b_0^2$, a constant. In Fig. 1 we plot the normalized rates $1/T_1\overline{b^2}\tau$ and $1/T_2\overline{b^2}\tau$ as a function of $\left|\vec{b}\right|/B_0$ for three values of $B_0\tau$: $B_0\tau = 0.1$, $B_0\tau = 1$ and $B_0\tau = 10$. First note that the correct perturbative limit is obtained when $\left|\vec{b}\right|/B_0 < 1$ and $B_0\tau < 1$ in Fig. 1(a). The standard transverse-noise relation $1/T_1 = 2/T_2$ holds over a fairly wide range: roughly $\left|\vec{b}\right|/B_0 \leq 3$, after which $1/T_1 > 2/T_2$. Stronger noise causes $1/T_1$ to be a super-quadratic function of $\overline{b^2}$, while the usual physical picture of dephasing ($1/T_2$) as due to a random walk in the phase variable appears to hold for all values of $\left|\vec{b}\right|/B_0$. As $B_0\tau$ increases, Fig. 1(b) and 1(c), we find that the relaxation rates decrease. This is not surprising: as τ increases, $k_{xx}(\omega) = k_{yy}(\omega)$ become sharply-peaked functions of ω, and the resonant processes responsible for the relaxation are suppressed. As the rates decrease, the $1/T_1 = 2/T_2$ holds over a braoder range of noise strength $\left|\vec{b}\right|/B_0$.

Secondly, we consider the case of isotropic noise: $\overline{b_x^2} = \overline{b_y^2} = \overline{b_z^2}$ with a uniform distribution of the solid angle and $b_x^2+b_y^2+b_z^2 = b_0^2$, a constant. In Fig. 2 we plot the normalized rates $1/T_1\overline{b^2}\tau$ and $1/T_2\overline{b^2}\tau$ as a function of $\left|\vec{b}\right|/B_0$ for the same three values of $B_0\tau$: $B_0\tau = 0.1$, $B_0\tau = 1$ and $B_0\tau = 10$. First note that the correct perturbative limit is obtained when $\left|\vec{b}\right|/B_0 < 1$ and $B_0\tau < 1$ in Fig. 2(a): the relation $1/T_1 = 1/T_2$ holds quite well for all values of noise strength $\left|\vec{b}\right|/B_0$, but both $1/T_1$ and $1/T_2$ are super-quadratic functions of $\overline{b^2}$. As $B_0\tau$ increases, the dephasing rate $1/T_2$ begins to dominate over the energy relaxation rate $1/T_1$. Figs. 2(b) and 2(c), the relaxation rates decrease for the same reasons as above. Interestingly, however, the $1/T_1 = 1/T_2$ relation is violated, presumably again due to the varying relative weights of $k_{xx}(\omega)$ and $k_{zz}(\omega = 0)$ as τ is increased.

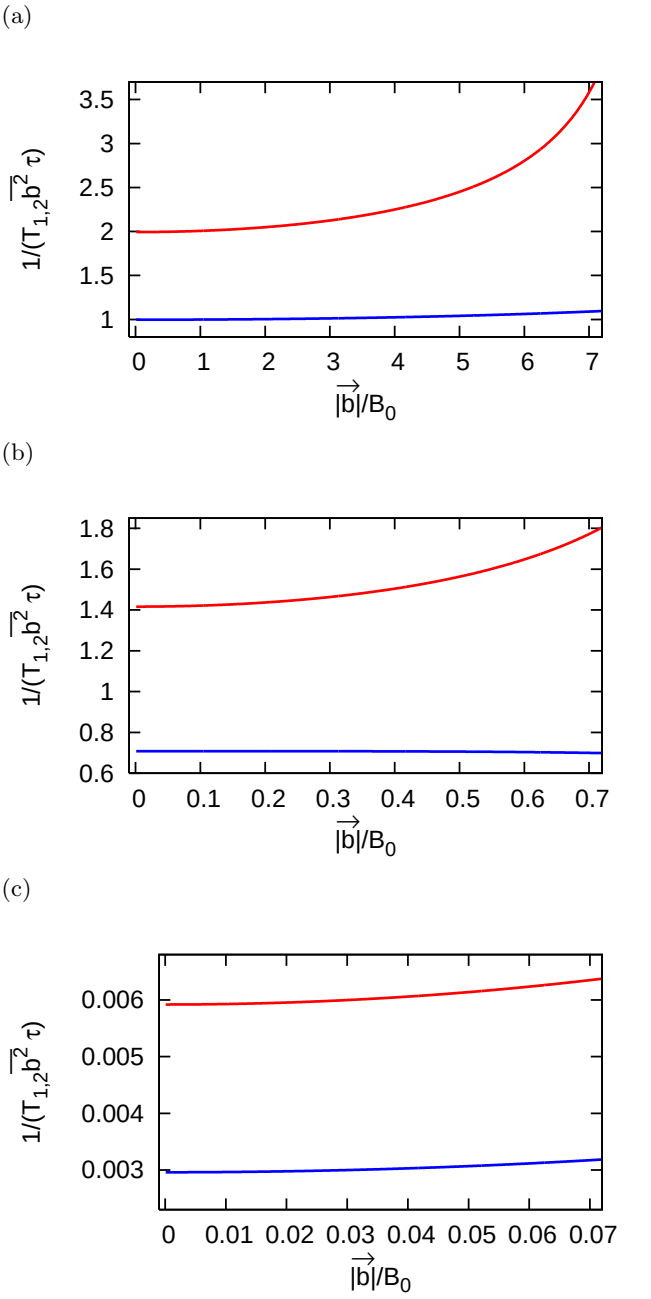

FIG. 1: $1/(T_{1,2}\overline{b^2}\tau)$ as functions of $\left|\vec{b}\right|/B_0$ for $\overline{b_x^2}$=$\overline{b_y^2}$ and $\overline{b_z^2} = 0$ with $B_0\tau = 0.1, 1$ and 10, corresponding to (a), (b) and (c) respectively. Upper (red) lines are for T_1 and lower (blue) lines for T_2.

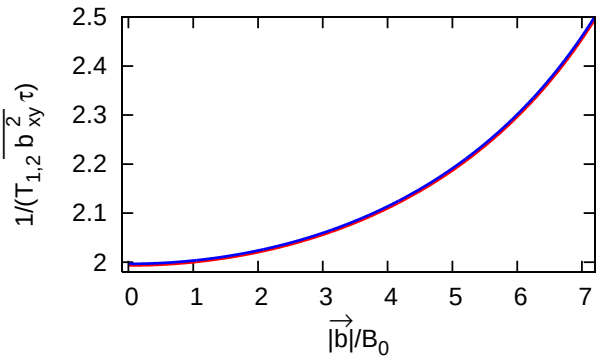
III. CORRELATED-NOISE MODELS

A. General solution

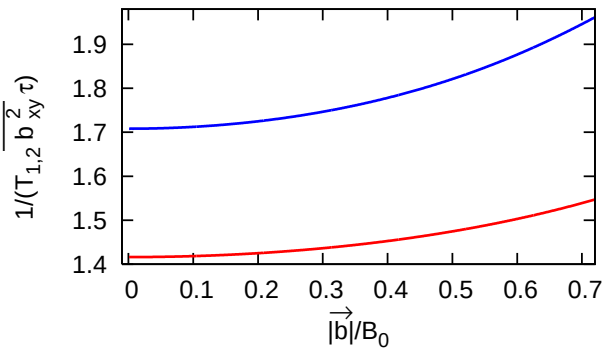
The Hamiltonian remains the same:

$$H = -B_0\sigma_z - \vec{b}(t)\cdot\vec{\sigma} = -\vec{B}\cdot\vec{\sigma},$$

(a)



(b)



(c)

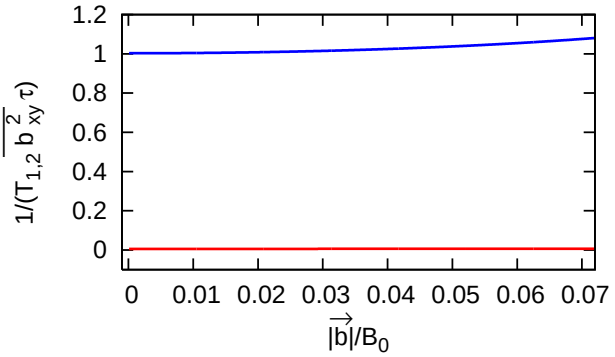


FIG. 2: $1/(T_{1,2}\overline{b^2_{xy}}\tau)$ with $\overline{b^2_{xy}} = \overline{b^2_x}+\overline{b^2_y}$ as functions of $\left|\vec{b}\right|/B_0$ for $\overline{b^2_x}$=$\overline{b^2_y}$ = $\overline{b^2_z}$ with $B_0\tau$ = 0.1, 1 and 10, corresponding to (a), (b) and (c) respectively. Lower (red) lines are for T_1 and upper (blue) lines for T_2.

and the piecewise constant time dependence of $\vec{b}(t)$ is retained. Now, however, successive values of $\vec{b}_i$ may be correlated. Thus we take the following model for $P(\vec{b}_1, \vec{b}_2, .., \vec{b}_m)$: the values of $\vec{b}_i$ are independent except for neighboring intervals, so we have

$$P(\vec{b}_1, \vec{b}_2, .., \vec{b}_m) = \Pi_{i=1,m=1} P(\vec{b}_i, \vec{b}_{i+1})$$

We shall make the natural assumption that $P(\vec{b}, \vec{b}')$ is symmetric: $P(\vec{b}, \vec{b}') = P(\vec{b}', \vec{b})$.

Now $\vec{\sigma}_{ij}$ transforms in the first interval into

$$\begin{aligned}\overline{\vec{\sigma}_{ij}(\tau)}(\vec{b}_2) &= \int d\vec{b}_1 P(\vec{b}_1, \vec{b}_2) \left[U_1^+(\tau)\right]_{ik} | \left[U_1(\tau)\right]_{lj} \vec{\sigma}_{kl} \\ &= \int d\vec{b}_1 P(\vec{b}_1, \vec{b}_2) \left[\exp iH_1\tau\right]_{ik} \left[\exp -i\vec{H}_1\tau\right]_{lj} \vec{\sigma}_{kl} \\ &= \int d\vec{b}_1 P(\vec{b}_1, \vec{b}_2) \\ &\quad \times \left[E\cos(B_1\tau) - i\widehat{B}_1\cdot\vec{\sigma}\sin(B_1\tau)\right]_{ik} \\ &\quad \times \left[E\cos(B_1\tau) + i\widehat{B}_1\cdot\vec{\sigma}\sin(B_1\tau)\right]_{lj} \vec{\sigma}_{kl},\end{aligned} \tag{26}$$

where E is the identity matrix and summation over repeated indices is implied. In matrix form, this is

$$\begin{aligned}\overline{\vec{\sigma}(\tau)}(\vec{b}_2) =& I_0(\vec{b}_2)\ \vec{\sigma} + \sum_{ij} I_{ij}(\vec{b}_2)\ \sigma_i\vec{\sigma}\sigma_j + \\ &+ i\sum_i I_i(\vec{b}_2)\ \left(\vec{\sigma}\sigma_i - \sigma_i\vec{\sigma}\right),\end{aligned} \tag{27}$$

where the integrals I_0, I_i and I_{ij} are defined as

$$\begin{aligned}I_0(\vec{b}') &= \int P(\vec{b}, \vec{b}')\cos^2(B\tau)\ d\vec{b} \\ I_i(\vec{b}') &= \int P(\vec{b}, \vec{b}')\widehat{B}_i\sin(B\tau)\cos(B\tau)\ d\vec{b} \\ I_{ij}(\vec{b}') &= \int P(\vec{b}, \vec{b}')\widehat{B}_i\widehat{B}_j\sin^2(B\tau)\ d\vec{b},\end{aligned}$$

analogously to the previous case.

We may write the evolution equations in a compact fashion by defining $f_0(\vec{b}) = \cos^2(B\tau)$, $f_i(\vec{b}) = \widehat{B}_i\sin(B\tau)\cos(B\tau)$, and $f_{ij}(\vec{b}') = \widehat{B}_i\widehat{B}_j\sin^2(B\tau)$, and $T_{xx}(\vec{b}) = f_0(b) + f_{xx}(\vec{b}) - f_{yy}(\vec{b}) - f_{zz}(\vec{b})$, etc., as in Eq. 7. Then we find

$$\vec{\sigma}(\vec{b}_2, \tau) = \int d\vec{b}_1 P(\vec{b}_2, \vec{b}_1) T(\vec{b}_1)\ \vec{\sigma}(0),$$

where $\vec{\sigma}$ is to be interpreted as a column matrix. When this process is iterated we have

$$\begin{aligned}\vec{\sigma}(\vec{b}_3, 2\tau) &= \int d\vec{b}_2 P(\vec{b}_3, \vec{b}_2) T(\vec{b}_2)\ \vec{\sigma}(\vec{b}_2, \tau) \\ &= \int d\vec{b}_2 P(\vec{b}_3, \vec{b}_2) T(\vec{b}_2) \\ &\quad \times \int d\vec{b}_1 P(\vec{b}_2, \vec{b}_1)\ T(\vec{b}_1)\ \vec{\sigma}(0),\end{aligned}$$

and finally

$$\begin{aligned}\vec{\sigma}(m\tau) = &\int d\vec{b}_{m+1} \int d\vec{b}_m P(\vec{b}_{m+1}, \vec{b}_m) T(\vec{b}_m) \cdots \times \\ &\int d\vec{b}_2 P(\vec{b}_3, \vec{b}_2) T(\vec{b}_2) \int d\vec{b}_1 P(\vec{b}_2, \vec{b}_1)\ T(\vec{b}_1)\ \vec{\sigma}(0).\end{aligned}$$

This problem is exactly soluble when the function $P(\vec{b},\vec{b}')$ is separable:

$$P(\vec{b},\vec{b}') = \sum_{n=1}^{N} p_n(\vec{b}) p_n(\vec{b}'). \tag{28}$$

This is of course not true for all functions $P(\vec{b},\vec{b}')$. However, if $P(\vec{b},\vec{b}')$ is continuous, it can be approximated uniformly by such an expression [11]. Substituting and converting to index notation with repeated indices summed, we have

$$\begin{aligned}\sigma_i(m\tau) = &\int d\vec{b}_{m+1} \int d\vec{b}_m p_{n_m}(\vec{b}_{m+1}) p_{n_m}(\vec{b}_m) T_{ii_m}(\vec{b}_m) \cdots \\ &\times \int d\vec{b}_2 p_{n_2}(\vec{b}_3) p_{n_2}(\vec{b}_2) T_{i_3 i_2}(\vec{b}_2) \\ &\times \int d\vec{b}_1 p_{n_1}(\vec{b}_2) p_{n_1}(\vec{b}_1)\ T_{i_2 j}(\vec{b}_1)\ \sigma_j(0).\end{aligned}$$

This can now be written as a matrix product

$$\sigma_i(m\tau) = \int d\vec{b}_{m+1} p_{n_m}(\vec{b}_{m+1}) S_{(n_m,i),(n_{m-1},i_m)} S_{(n_{m-1},i_m),(n_{m-2},i_{m-1})} \cdots S_{(n_2,i_3),(n_1,i_2)} \int d\vec{b}_1 p_{n_1}(\vec{b}_1)\ T_{i_2 j}(\vec{b}_1)\ \sigma_j(0), \tag{29}$$

where we have defined the $3N \times 3N$ matrix

$$S_{(n',i),(n'',j)} = \int d\vec{b}\ p_{n'}(\vec{b}) T_{ij}(\vec{b}) p_{n''}(\vec{b}). \tag{30}$$

Diagonalizing S, we have the solution

$$\begin{aligned}\sigma_i(m\tau) = &\int d\vec{b}' F_n(\vec{b}')\ \left(S^{m-1}\right)_{(n,i),(n',j)} \times \\ &\int d\vec{b}\ F_{n'}(\vec{b}) T_{jk}(\vec{b})\ \sigma_k(0) \\ = &\int d\vec{b}' F_n(\vec{b}') \left\{R_S^{-1}\left[diag(S)^{m-1}\right] R_S\right\}_{(n,i),(n',j)} \\ &\times \int d\vec{b}\ F_{n'}(\vec{b}) T_{jk}(\vec{b})\ \sigma_k(0).\end{aligned} \tag{31}$$

Here R_S is the matrix whose rows are the eigenvectors of S, and $diag(S)$ is the diagonal matrix with the eigenvalues of S along the diagonal. The relaxation times are then obtained by the same arguments as in the previous section, except now they must be obtained by computing the eigenvalues of S, not T. The matrices enclosing $diag(S)^{m-1}$ determine how to prepare and measure the system if one wishes to determine some particular relaxation time.

B. Example

In the first example, the scattering was purely s-wave: isotropic in ϕ. If the scattering can also occur in the p-wave channel, then the successive values of $\vec{b}$ are correlated. An interesting example is a mixture of s-wave and p-wave given by

$$P(\vec{b},\vec{b}') = \frac{1}{2\pi b_0}\delta(b-b_0)\delta(b_z)\left[1 + r\cos\left(\phi-\phi'\right)\right], \tag{32}$$

with $0 \le r \le 1$. We choose this model partly because of its simplicity. However, it also has some interesting physics. For $r = 0$ it reduces to the previous example. For $r = 1$, there is suppression of backscattering at $\phi - \phi' = \pi$. This implies that, as r increases, the problem crosses over from a purely random walk in spin space to one in which the successive steps tend to be in the same direction.

After performing the integrals over the $\left|\vec{b}_i\right|$ and b_{iz}, we find

$$\begin{aligned}P(\phi,\phi') &= \frac{1}{2\pi}\left[1 + r\cos\left(\phi-\phi'\right)\right] \\ &= \frac{1}{2\pi}\left(1 + r\cos\phi\cos\phi' + r\sin\phi\sin\phi'\right)\end{aligned} \tag{33}$$

so that the function is separable

$$P(\phi,\phi') = \sum_{n=1}^{3} p_n(\phi) p_n(\phi') \tag{34}$$

with

$$p_1(\phi) = \sqrt{\frac{1}{2\pi}},\ p_2(\phi) = \sqrt{\frac{r}{2\pi}}\cos\phi,\ p_3(\phi) = \sqrt{\frac{r}{2\pi}}\sin\phi. \tag{35}$$

We now need to compute the 9×9 matrix

$$S_{(ni),(n'j)} = \int d\phi\ p_n(\phi) T_{ij}(\phi) p_{n'}(\phi). \tag{36}$$

We are interested here in the decoherence limit: $b_0\tau << B_0\tau << 1$. The integrations over the angular functions

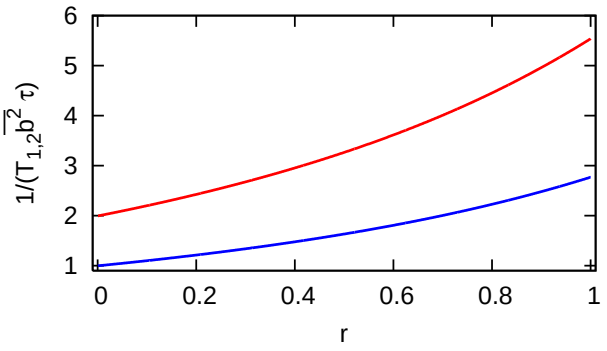

FIG. 3: $1/(T_{1,2}\overline{b^2}\tau)$ as functions of r. The upper (red) line is for T_1 and the lower (blue) one for T_2.

are elementary. The nonzero elements of S are

$$
\begin{aligned}
S_{(1x),(1x)} &= S_{(1y),(1y)} = 1 - 2B_0^2\tau^2 - b_0^2\tau^2 \\
S_{(2x),(2x)} &= S_{(3y),(3y)} = (r/2)\left(1 - 2B_0^2\tau^2\right) - rb_0^2\tau^2/2 \\
S_{(3x),(3x)} &= S_{(2y),(2y)} = (r/2)\left(1 - 2B_0^2\tau^2\right) - 3rb_0^2\tau^2/4 \\
S_{(1z),(1z)} &= 1 - 2b_0^2\tau^2 \\
S_{(2z),(2z)} &= S_{(3z),(3z)} = (r/2)\left(1 - 2b_0^2\tau^2\right) \\
S_{(1x),(1y)} &= -S_{(1y),(1x)} = 2B_0\tau \\
S_{(2x),(2y)} &= S_{(3x),(3y)} = -S_{(2y),(2x)} = -S_{(3y),(3x)} = rB_0\tau \\
S_{(2x),(3y)} &= S_{(2x),(3y)} = S_{(2y),(3x)} = S_{(2y),(3x)} = rb_0^2\tau^2/2 \\
S_{(1x),(2z)} &= S_{(2x),(1z)} = S_{(1z),(2x)} = S_{(2z),(1x)} \\
&= S_{(1y),(3z)} = S_{(3y),(1z)} = S_{(1z),(3y)} \\
&= S_{(3z),(1y)} = \sqrt{r}b_0B_0\tau^2/2 \\
S_{(1x),(3z)} &= S_{(3x),(1z)} = -S_{(1y),(2z)} = -S_{(2y),(1z)} \\
&= -S_{(1z),(3x)} = -S_{(3z),(1x)} = S_{(1z),(2y)} \\
&= S_{(2z),(1y)} = -\sqrt{r}b_0\tau/2
\end{aligned}
$$

This matrix is easily diagonalized numerically, and the results are shown in Fig. 3. All eigenvalues are less than one in magnitude, as before. Six of these eigenvalues are much less than 1, and correspond to transients. Two (one) give finite relaxation times when t_f/τ becomes large and correspond to T_2 (T_1). $1/T_1$ increases from $2b_0^2\tau$ to about 5.9 $b_0^2\tau$, and $1/T_2$ increases from $b_0^2\tau$ to 2.5 $b_0^2\tau$ as x goes from 0 to 1. This is to be expected, as decrease in the average angle of change of the field corresponds intuitively to a longer step in the random walk of the spin vector.

IV. DISCUSSION

The two basic features that make the basic white-noise-like model solvable is that (1) the noise Hamiltonian is piecewise constant with equal intervals and that (2) the system space is two-dimensional. These features limit the applicability of the model.

Condition (1) is a fairly severe limitation: often, the effectiveness of the noise is related to $k_{ii}(\omega_0)$. In the basic model, this can only be varied by changing the parameter $B_0\tau$. The *shape* of $k_{ii}(\omega_0)$ is fixed in the white noise model, and can only be changed to a limited extent by going over to correlated-noise generalizations. Some very interesting problems, such as the effect of $1/f$ noise on qubits [12], appear to be outside the scope of this method. It may be possible to allow for a distribution of intervals without sacrificing solvability - the multiple time integral thus obtained, though complicated, may be susceptible to integral transform techniques.

Condition (2) is not easily jettisoned. The three Pauli matrices generate the 3-dimensional algebra of $SU(2)$, T generates orbits in this algebra, and this implies that T is a 3×3 matrix. The transformations of a three-dimensional Hilbert space (for a qtrit) belong to $SU(3)$, and the algebra is an 8-dimensional space. Hence the transfer T matrix for this problem would be 8×8. There may be special situations in which there is an exact solution. The solution of the two-dimensional Ising model depends on diagonalizing a $2^N \times 2^N$ transfer matrix, where N is the number of spins in the transverse direction. The corresponding generalization of the present problem would require the diagonalization of an $N^2 - 1 \times N^2 - 1$ matrix for an N-level system. $N^2 - 1$ is the number of generators of $SU(N)$. Such a generalization is likely to require some new ideas.

Despite these limitations, the method is new and susceptible to development in different directions. It should serve as an important tool in the study of decoherence in the future.

We would like to acknowledge useful converstaions with C. Tahan and M. Friesen, and the support of the NSF ITR program.

V. APPENDIX

Here we show that the eigenvalues satisfy $|d_3| \leq 1$ and $|d_\pm| \leq 1$.

Theorem: $|d_\pm| \leq 1$.

Proof:

$$\begin{aligned}
|d_\pm|^2 &= \left| I_0 - I_{zz} \pm i\sqrt{4I_z^2 - (I_{xx}-I_{yy})^2} \right|^2 \\
&= (I_0 - I_{zz})^2 + 4I_z^2 - (I_{xx}-I_{yy})^2 \\
&\leq (I_0 - I_{zz})^2 + 4I_z^2 \\
&= \left\{ \int P(\vec{b}) \left[\cos^2(B\tau) - \widehat{B}_z \sin^2(B\tau) \right] d^3b \right\}^2 + \\
&\quad + 4 \left[\int P(\vec{b}) \widehat{B}_z \sin(B\tau)\cos(B\tau)\, d^3b \right]^2 \\
&\leq \int \left[\cos^2(B\tau) - \widehat{B}_z \sin^2(B\tau) \right]^2 P(\vec{b}) d^3b + \\
&\quad + 4 \int \left[\widehat{B}_z \sin(B\tau)\cos(B\tau) \right]^2 P(\vec{b}) d^3b,
\end{aligned}$$

where the final inequality is an application of the Schwarz inequality. Since $\left|\widehat{B}_z\right| \leq 1$, we also have

$$\begin{aligned}
|d_\pm|^2 &\leq \int \left[\cos^2(B\tau) - \widehat{B}_z \sin(B\tau) \right]^2 P(\vec{b})\ d^3b + \\
&\quad + 4 \int \left[\widehat{B}_z \sin(B\tau)\cos(B\tau) \right]^2 P(\vec{b})\ d^3b \\
&= \int \left[\cos^2(B\tau) + \widehat{B}_z \sin^2(B\tau) \right]^2 P(\vec{b})\ d^3b \\
&\leq \int \left[\cos^2(B\tau) + \sin^2(B\tau) \right]^2 P(\vec{b})\ d^3b \\
&= \int P(\vec{b})\ d^3b \\
&= 1.
\end{aligned}$$

Theorem: $|d_3| \leq 1$.

Proof:

$$\begin{aligned}
d_3 &= I_0 - I_{xx} - I_{yy} + I_{zz} \\
&= \int P(\vec{b}) \left[\cos^2(B\tau) + \left(\widehat{B}_z^2 - \widehat{B}_x^2 - \widehat{B}_y^2 \right) \sin^2(B\tau) \right] d^3b \\
&\leq \int P(\vec{b}) \left[\cos^2(B\tau) + \widehat{B}_z^2 \sin^2(B\tau) \right] d^3b \\
&\leq \int P(\vec{b}) \left[\cos^2(B\tau) + \sin^2(B\tau) \right] d^3b \\
&= 1,
\end{aligned}$$

and recalling that $\widehat{B}_z^2 + \widehat{B}_x^2 + \widehat{B}_y^2 = 1$, we also have

$$\begin{aligned}
d_3 &= \int P(\vec{b}) \left[\cos^2(B\tau) + \left(\widehat{B}_z^2 - \widehat{B}_x^2 - \widehat{B}_y^2 \right) \sin^2(B\tau) \right] d^3b \\
&= \int P(\vec{b}) \left\{ \cos^2(B\tau) + \left[1 - 2\left(\widehat{B}_x^2 + \widehat{B}_y^2 \right) \right] \sin^2(B\tau) \right\} d^3b \\
&= 1 - 2 \int P(\vec{b}) \left[\cos^2(B\tau) + \sin^2(B\tau) \left(\widehat{B}_x^2 + \widehat{B}_y^2 \right) \right] d^3b \\
&\geq 1 - 2 \int P(\vec{b}) \left[\cos^2(B\tau) + \sin^2(B\tau) \right] d^3b \\
&= -1.
\end{aligned}$$

Hence $|d_3| \leq 1$.
